Received July 28, 2000; revised October 31, 2000; published online March 8, 2001

Phylogenetic relationships among frogs of the genus Rana from western North America are investigated using 2013 aligned bases of mitochondrial DNA sequence from the genes encoding ND1 (subunit one of NADH dehydrogenase), tRNA18S, tRNA21N, tRNAAla, ND2, tRNA17P, tRNAAsn, trNA14s, tRNA13C, tRNA16R, and COI (subunit I of cytochrome c oxidase), plus the origin for light-strand replication (O1) between the tRNAAsn and tRNACys genes. The aligned sequences contain 401 phylogenetically informative characters. A well-resolved phylogenetic hypothesis in which the Rana boylii species group (R. aurora, R. boylii, R. cascadae, R. muscosa, and R. pretiosa) is monophyletic is obtained. Molecular sequence divergence suggests that the R. boylii species group is approximately 8 million years old. The traditional hypothesis showing monophony of the yellow-legged frogs (R. boylii and R. muscosa) is statistically rejected in favor of a hypothesis in which R. aurora, R. cascadae, and R. muscosa form a clade. Reanalyses of published nuclear ribosomal DNA restriction-site data and allozymic data support a monophyletic R. boylii group, but do not effectively resolve relationships among species within this group. Eight populations of R. muscosa form two major clades separated by a biogeographic break in the Sierra Nevada of California. This biogeographic break is broadly concordant with breaks found in four other amphibian and reptilian taxa. The two major clades within R. muscosa are estimated to have diverged approximately 2.2 million years before present. Each of these major clades contains two subgroups showing approximately 1.5 million years divergence, implicating climatic effects of Pleistocene glaciation in vicariance. The four distinct subgroups of R. muscosa separated by at least 1.4 million years of evolutionary divergence are suggested as potential units for conservation. © 2001 Academic Press

Key Words: Amphibia; Anura; Ranidae; Rana; North America; California; biogeography; mitochondrial DNA; phylogenetics.

Five species of frogs in the family Ranidae occur strictly in western North America. These five species, Rana aurora, R. boylii, R. cascadae, R. muscosa, and R. pretiosa (here termed the R. boylii species group; Case, 1978), show variation in leg coloration, size, and elevational distribution. Phylogenetic relationships among the five species are a major subject of debate among evolutionary biologists (see Green, 1986b for a review). Despite numerous studies involving albumin immunology (Case, 1978; Farris et al., 1979, 1982; Post and Uzzell, 1981; Wallace et al., 1973), allozyme electrophoresis (Case, 1978; Green, 1986b), chromosomes (Green, 1986a), and restriction-enzyme cleavage analysis of nuclear rRNA genes (Hillis and Davis, 1986), no phylogenetic consensus has been achieved.

A long-standing view among biologists is that the two yellow-legged frogs, R. boylii (with a smaller body size and occurring at low elevation primarily in California) and R. muscosa (with a larger body size and occurring strictly at high elevations in California), form a monophyletic group (Green, 1986a,b; Zweifel, 1955). The red-legged frog, R. aurora (which has a relatively large body size) is found in low-elevation areas along the Pacific coast and is often not grouped with the two yellow-legged frog species (Green, 1986a,b; Zweifel, 1955). The other two species of western North American ranids occur at high elevations. R. cascadae (which has a relatively large body size) is found in the Cascade Range from northern California to Washington, and R. pretiosa (which has a relatively small body size and is sometimes divided into two species, R. pretiosa to the west and R. luteiventris to the east; Green et al., 1997) is found in the interior montane regions of northwestern North America. R. cascadae and R. pretiosa lack distinctive leg coloration and are not grouped with the two yellow-legged frog

species (R. boylii and R. muscosa) under the traditional view of systematic relationships (Green, 1986a,b; Zweifel, 1955).

An additional subject of debate concerns monophyly of the R. boylii species group with respect to the Eurasian R. temporaria species group and the North American species R. sylvatica (Case, 1978; Farris et al., 1979, 1982; Green, 1986b; Hillis and Davis, 1986; Post and Uzzell, 1981). The three main hypotheses proposed are: (1) the R. boylii species group represents a monophyletic taxon (Case, 1978; Hillis and Davis, 1986; Post and Uzzell, 1981; Uzzell and Post, 1986), (2) the R. temporaria species group is nested within the R. boylii species group (Farris et al., 1979, 1982), and (3) R. sylvatica is nested within the R. boylii species group (Dumas, 1966). All other Rana are considered only distantly related to the R. boylii species group (reviewed by Hillis and Davis, 1986).

Phylogenetic relationships of the five species of the R. boylii species group were examined using a 2013-base region of the mitochondrial genome spanning from the protein-coding gene ND1 (subunit one of NADH dehydrogenase) through the genes encoding tRNA^{Leu}_{AGU}, tRNA^{Ser}_{UCA}, tRNA^{Met}_{GUG}, ND2, tRNA^{Ala}_{UAC}, tRNA^{Asn}_{AAC}, tRNA^{Glu}_{UCA}, tRNA^{Thr}_{ACU}, and tRNA^{Trp}_{AGA}, to the protein-coding gene COI (subunit I of cytochrome c oxidase), and including the replication origin for the light strand (O_{L}) between the tRNA^{Asn} and the tRNA^{Glu} genes. Monophyly of the R. boylii species group is tested with three outgroup taxa, R. catesbeiana, R. sylvatica, and R. temporaria. The R. boylii species group may be paraphyletic with respect to the R. temporaria group from Europe (Farris et al., 1979, 1982), in which R. sylvatica from North America is sometimes placed (Hillis and Davis, 1986). The eastern North American taxon, R. catesbeiana, is a standard outgroup taxon used in previous molecular phylogenetic studies and is included for consistency.

In California, a pattern of biogeographic fragmentation between northern and southern populations is emerging among codistributed species of amphibian and reptilian taxa in the Sierra Nevada [the salamanders, Ensatina eschscholtzii (Moritz et al., 1992) and Taricha torosa (Tan and Wake, 1995); a frog, Bufo canorus (Shaffer et al., 2000); and a snake, Lampropeltis zonata (Rodríguez-Robles et al., 1999)]. Eight populations within R. muscosa spanning the complete range of the species were sampled from California to examine the effect of this geographic break on the species. This species is nearing extinction in the northern Sierra Nevada, central Sierra Nevada, and southern California, and the results of this study may have management implications. Previously, populations from the Sierra Nevada have been considered a subspecies, R. muscosa sierrae (Camp, 1917), distinct from populations in southern California referred to as R. muscosa muscosa.

We reanalyze the existing allozymic data (Case, 1978; Green, 1986b) and variation in restriction-enzyme cleavage sites in nuclear rRNA genes (Hillis and Davis, 1986) in light of our newly published data.

**MATERIALS AND METHODS**

**Specimen Information**

Museum numbers and localities for voucher specimens from which DNA was extracted and GenBank accession numbers are presented below. Acronyms are CAS for California Academy of Sciences, San Francisco and MVZ for Museum of Vertebrate Zoology, University of California at Berkeley. An acronym followed by a dash RM represents a field number of the first author for an uncatalogued specimen being deposited in the Museum of Vertebrate Zoology. The population of R. sylvatica was introduced from Warren Co., Missouri, and the R. aurora population sampled is thought to have been introduced from Contra Costa Co., California (Green, 1985). The R. pretiosa population sampled is sometimes considered to belong to a distinct species, R. lutiventris (Green et al., 1997).

ft., North Fork San Jacinto River, San Jacinto Mountains, Riverside Co., California. (8) MVZ 230141, AF314030, elev. 1880 ft., East Fork City Creek, San Bernardino Mountains, San Bernardino Co., California.

Laboratory Protocols

Genomic DNA was extracted from liver using the Qiagen QIAamp tissue kit. Amplification of genomic DNA was conducted using a denaturation at 94°C for 35 s, annealing at 50°C for 35 s, and extension at 70°C for 150 s with 4 s added to the extension per cycle, for 30 cycles. Negative controls were run for all amplifications. Amplified products were purified on 2.5% acrylamide gels (Maniatis et al., 1982). Template DNA was eluted from acrylamide gels and reamplified under similar conditions. Reamplified double-stranded products were purified on 2.5% acrylamide gels (Maniatis et al., 1982). Template DNA was eluted from acrylamide gel passively over 3 days with Maniatis elution buffer (Maniatis et al., 1982). Cycle-sequencing reactions were run using the Promega fmol DNA-sequencing system with a denaturation at 95°C for 35 s, annealing at 45–60°C for 35 s, and extension at 70°C for 1 min for 30 cycles. Sequencing reactions were run on Long Ranger sequencing gels for 5–12 h at 38–40°C.

Amplifications from genomic DNA were done using different primer combinations (Table 1): (1) L2507–H4419, (2) L3914–H4980, and (3) L4437–H6564. In addition, H5934 was used in combination with the following light-strand primers: L2948, L3914, L4160, L4221, and L4437. Both strands were sequenced using the primers in Table 1. Primer numbers refer to the 3’ end on the human mitochondrial genome (Anderson et al., 1981), where L and H correspond to primers whose extension produces light and heavy strands, respectively.

Phylogenetic Analysis

DNA sequences were aligned manually. Protein-coding sequences were translated to amino acids using MacClade (Maddison and Maddison, 1992) for confirmation of alignment. Transfer-RNA secondary structure was determined manually using the criteria of Kumazawa and Nishida (1993) to ensure proper alignment.

Phylogenetic trees were estimated using PAUP* beta version 4.0b2 (Swofford, 1999) with branch-and-bound searches. Bootstrap resampling was applied to assess support for individual nodes with 500 bootstrap replicates using branch-and-bound searches. Bootstrap analysis of the allozymic data of Green (1986b) using allelic combinations as character states with step matrices featured 10 heuristic searches with random addition of sequences per bootstrap replicate. Decay indices (= “branch support” of Bremer, 1994) were calculated for all internal branches of the trees as follows. Branch-and-bound searches, which retained suboptimal trees, were run for all nodes; the decay index was then tabulated as the difference in length between the shortest tree that did not contain a particular node and the overall shortest tree.

The Wilcoxon signed-ranks test (Felsenstein, 1985;
Templeton, 1983) was used to examine statistical significance of the overall shortest tree relative to alternative hypotheses. This test asks whether the most parsimonious tree is significantly shorter than an alternative or whether their differences in length can be attributed to chance alone (Larson, 1998). Wilcoxon signed-ranks tests were conducted as one- and two-tailed tests. Felsenstein (1985) showed that one-tailed probabilities are close to the exact probabilities for this test but not always conservative, whereas the two-tailed test is always conservative. Tests were conducted using PAUP* beta version 4.0b2 (Swofford, 1999), which incorporates a correction of tied ranks. When appropriate, the large-sample approximation for probabilities given in PAUP* (Swofford, 1999) was used. For comparisons among R. muscosa populations, for which the large-sample approximation is not appropriate, statistical significance was determined using Table A.4 from Hollander and Wolfe (1973).

Alternative phylogenetic hypotheses were tested using the most parsimonious phylogenetic topologies compatible with them. To find the most parsimonious tree(s) compatible with a particular phylogenetic hypothesis, phylogenetic topologies were constructed using MacClade (Maddison and Maddison, 1992) and analyzed as constraints using PAUP* beta version 4.0b2 (Swofford, 1999) with branch-and-bound searches.

Cladistic Analyses of Allozymic Data

Previously reported allozymic data of Case (1978) and Green (1986b) were coded in two ways for cladistic phylogenetic analysis. Although presence–absence coding of alleles has received considerable criticism for a lack of independence of alleles and the possibility of no allele being reconstructed for an ancestral node, it remains the method that provides the greatest amount of resolution (see Macey et al., 1999a). Alternatively, combinations of alleles for a particular locus may be coded as discrete character states (Buth, 1984). If step matrices are used to connect character states, a greater amount of information can be retained (Maibe and Humphries, 1993). In our analysis, step matrices were constructed on the basis of gains and losses of alleles. For example, a fixed difference between two alleles was counted as two steps, one allele lost and another gained. In the case of a two-allele polymorphism in one population with one allele shared with another monomorphic population, a single gain or loss was counted as a single step. Additional polymorphisms were counted in the same manner. Our analysis excluded alleles scored as absent (“abs”) by Case (1978).

RESULTS

Sequences ranging in size from 2008 to 2012 bases of mitochondrial DNA for 15 taxa of Rana are aligned as 2013 positions. Sequences reported here correspond to positions 3892 to 5936 on the human mitochondrial genome (Anderson et al., 1981) and contain the genes encoding ND1 (subunit one of NADH dehydrogenase), tRNAThr, tRNAAsn, tRNAMet, ND2, tRNATrp, tRNAHis, tRNAAsn, tRNACys, tRNAAsp, and COI (subunit I of cytochrome c oxidase), plus the O1 between the tRNAAsp and tRNAAsp genes. Length variation is minimal in this data set, and all 2013 aligned positions were analyzed phylogenetically. The second-to-last codon position in the ND2 gene is absent in the R. muscosa populations sampled; three gaps are placed at positions 1601–1603. Among tRNA genes, length variation is observed only in the sequences encoding the TuC (T) loop of tRNAThr. The R. muscosa sample from the San Jacinto Mountains has a sequence 1 base longer, and the R. muscosa sample from Fresno County has a sequence 1 base shorter, than the sequences derived from other taxa sampled. A single gap is placed at position 1929 in all sequences except the sequence derived from the San Jacinto Mountains sample of R. muscosa. An additional gap is placed at position 1928 in the sequence derived from the Fresno County sample of R. muscosa. Between the tRNAAsp and the tRNAAsp genes, a single gap is placed at position 1749 in the three outgroup taxa (R. catesbeiana, R. sylvatica, and R. temporaria). In the origin of light-strand replication (O1), a gap is placed at position 1836 in the R. catesbeiana sequence, and a gap is placed at position 1835 in the R. boylii sequence.

Authentic Mitochondrial DNA

Several observations suggest that the DNA sequences analyzed here are from the mitochondrial genome and do not represent nuclear-integrated copies of mitochondrial genes (see Zhang and Hewitt, 1996). Protein-coding genes do not have premature stop codons, suggesting that these sequences represent functional copies that encode a protein. Transfer-RNA genes appear to code for tRNAs with stable secondary structures, indicating functional genes. The presence of strand bias further supports our conclusion that the 15 DNA sequences reported here are from the mitochondrial genome. The sequences reported here show strong strand bias against guanine on the light strand (G = 12.6–14.1%, A = 26.5–28.3%, T = 28.7–31.0%, and C = 27.8–30.9%), which is characteristic of the mitochondrial genome but not the nuclear genome. See Macey et al. (1998b) for similar strand bias in bufonid frogs for the same region of the mitochondrial genome.

Genic Variation

Different levels of DNA substitutional variation are observed among the three protein-coding genes, eight tRNA-coding genes, and three noncoding regions (Table 2). All of the genes sequenced except the tRNAAsp gene contain phylogenetically informative characters. The ND1 and ND2 protein-coding genes contain phy-
logenetic information in first, second, and third codon positions. Most of the variation and phylogenetically informative sites are from protein-coding regions. Only 13% of variable and 12% of phylogenetically informative sites are from tRNA genes and noncoding regions.

Of the 354 phylogenetically informative characters from protein-coding regions, 264 are from third positions of codons. Third-position sites account for approximately two thirds of the phylogenetically informative sites in the total data set. Only 23 phylogenetically informative sites occur in regions encoding stems of tRNAs, suggesting that compensatory substitutions do not compromise the phylogenetic analysis.

**Phylogenetic Relationships**

A single tree results from the parsimony analysis of the 2013 aligned DNA sequences containing 401 phylogenetically informative base positions (Fig. 1, Table 2). Phylogenetic relationships are well resolved for most nodes of the tree. Relative to *R. catesbeiana* and *R. sylvatica*, *R. temporaria* appears as the sister taxon (bootstrap 96%; decay index 18) to a monophyletic *R. boylii* group (bootstrap 96%; decay index 13). Within the *R. boylii* group, *R. boylii* and *R. pretiosa* are weakly supported as sister species (decay index 1). They form the sister taxon to a well-supported clade containing *R. aurora*, *R. cascadae*, and *R. muscosa* populations (bootstrap 95%; decay index 8). Within this clade, relationships among species are not well resolved, but *R. cascadae* and *R. muscosa* appear as sister taxa (bootstrap 54%; decay index 3).

Among *R. muscosa* populations, two major clades are evident: a northern group (bootstrap 88%; decay index 6) consisting of samples from Plumas, Alpine, and Tuolumne Counties of California in the Sierra Nevada, and a southern group (bootstrap 92%; decay index 7) consisting of samples from the southern Sierra Nevada, the San Gabriel Mountains, the San Jacinto Mountains, and the San Bernardino Mountains of southern California. Within the northern clade, populations from Plumas County in the northern Sierra Nevada form a well-supported clade (bootstrap 100%; decay index 1), and populations in the central Sierra Nevada also form a well-supported clade (bootstrap 100%; decay index 12). In the southern clade, the population from Fresno County in the southern Sierra Nevada also form a well-supported clade (bootstrap 100%; decay index 12). The relationships between the three southern California populations are not well resolved, with the San Gabriel and San Jacinto mountain populations grouped together (bootstrap 64%; decay index 1).

produces a single most parsimonious tree (Fig. 2). Relationships are not well supported, with all branches in the tree having decay indices of only 1 or 2. The topology is not the same as that produced from the mitochondrial DNA sequences, although the \( R. \) boylii group is monophyletic, and the yellow-legged frogs (\( R. \) boylii and \( R. \) muscosa) do not form a monophyletic group.

Phylogenetic relationships from reanalysis of allozymic data (Case, 1978; Green, 1986b) are largely the same whether analyzed with allelic combinations as character states using step matrices or as presence/absence coding of alleles (Fig. 3). The allozymic data of Case (1978) recover a single most parsimonious tree in all analyses, with poor support for phylogenetic relationships among species. The topology differs from results of other data sets, although the \( R. \) boylii group is monophyletic and the yellow-legged frogs (\( R. \) boylii and \( R. \) muscosa) do not form a monophyletic group.

The allozymic data of Green (1986b) recover two equally most parsimonious trees in the analysis applying the presence or absence of alleles, whereas the analysis of allelic combinations as character states with step matrices produces three equally most parsimonious trees (Fig. 4). The two trees found in the former analysis also appear in the latter analysis. These trees differ in topology from results of other data sets; however, both analyses recover a monophyletic \( R. \) boylii group. Phylogenetic positions of the yellow-legged species (\( R. \) boylii and \( R. \) muscosa) are not well resolved, with only the analysis applying the presence or absence of alleles weakly suggesting grouping of the two species. These trees differ from the trees derived from mitochondrial DNA sequences, the nuclear RNA restriction-site data of Hillis and Davis (1986), and the allozymic data of Case (1978).

Phylogenetic results derived from analyses of mitochondrial DNA sequences provide a more robust estimate of relationships than previously published data. The phylogenetic hypothesis derived from mitochondrial DNA sequences (Fig. 1) is tested against alternative topologies by applying the Wilcoxon signed-ranks test.
(1). All analyses presented here support monophyly of the R. boylii group. The shortest alternative tree in which the R. boylii group is not monophyletic (A1 in Appendix) cannot be rejected in favor of the overall shortest tree (Fig. 1), although this test is close to significance using the one-tailed test (test 1 in Table 3).

(2). Only the analysis applying the presence or absence of alleles from Green (1986b) suggests that R. boylii and R. muscosa are sister taxa. The mitochondrial DNA data reject the shortest alternative tree (B1 in Appendix) showing R. boylii and R. muscosa as a monophyletic group in favor of the overall shortest tree (Fig. 1) using the two-tailed test (test 2 in Table 3).

(3). The DNA sequence data presented here do not support monophyly of Sierra Nevada populations of R. muscosa. The shortest alternative tree (C1 in Appendix) showing Sierra Nevada populations of R. muscosa as a monophyletic group is rejected in favor of the overall shortest tree (Fig. 1) using the one-tailed test (test 3 in Table 3).

(4). The DNA sequence data suggest that the northern Sierra Nevada populations of R. muscosa form a
clade. The shortest alternative tree (D1 in Appendix) in which northern Sierra Nevada populations of R. muscosa do not form a monophyletic group is rejected in favor of the overall shortest tree (Fig. 1) using the two-tailed test (test 4 in Table 3).

(5). The DNA sequence data suggest that the central Sierra Nevada populations of R. muscosa form a clade. The shortest alternative tree (E1 in Appendix) in which central Sierra Nevada populations of R. muscosa do not form a monophyletic group is rejected in favor of the overall shortest tree (Fig. 1) using the two-tailed test (test 5 in Table 3).

(6). The DNA sequence data suggest that southern California populations of R. muscosa form a clade. The shortest alternative tree (F1 in Appendix) in which southern California populations of R. muscosa do not form a monophyletic group is rejected in favor of the overall shortest tree (Fig. 1) using the two-tailed test (test 6 in Table 3).

Because the ribosomal DNA restriction-site data and allozymic data provide few phylogenetically informative characters and only weak branch support for their favored topologies (Figs. 2–4), further statistical analysis of these data is not warranted.

**DISCUSSION**

All phylogenetic analyses of the mitochondrial DNA sequence data, nuclear restriction-site data, and allozymic data suggest that the R. boylii group is monophyletic. The DNA sequence data show strong support for this hypothesis, with a bootstrap value of 96% and a decay index of 13. Although the alternative hypothesis of a nonmonophyletic R. boylii group cannot be rejected using the Wilcoxon signed-ranks test, the P value is almost significant (P = 0.07; Table 3). Our results supporting monophyly of the R. boylii group agree with the albumin immunological studies of Case (1978) and Post and Uzzell (1981) and conflict with conclusions drawn from reanalyses of those data by Farris et al. (1979, 1982).

The mitochondrial DNA sequence data suggest that R. aurora, R. cascadae, and R. muscosa form a clade within the R. boylii species group, but do not strongly resolve other interspecific relationships within this group. The phylogenetic analyses of the nuclear restriction-site data, allozymic data, and mitochondrial DNA sequence data all produce different topologies within the R. boylii species group. The nuclear restriction-site and allozymic data provide poor support for phylogenetic relationships among these species. Only the reanalysis using the presence/absence of alleles as character states in the allozymic data of Green (1986a) with questionable homology of character states support a sister taxon relationship of R. boylii and R. muscosa. Published data therefore provide little support for monophyly of a group comprising the yellow-legged frogs. The mitochondrial DNA sequence data strongly reject the grouping of R. boylii with R. muscosa using the Wilcoxon signed-ranks test (Table 3).

**Age of the R. boylii Species Group**

The region of mitochondrial DNA sequenced has been found to evolve with an approximately consistent rate of change per lineage per million years among a wide range of vertebrates [fish 0.65% (Bermingham et
al., 1997); hynobiid salamanders 0.64% (unpublished data of the authors); frogs of the genus Bufo 0.69% (Macey et al., 1998b); lizards of the genus Laudakia 0.65% (Macey et al., 1998a); lizards of the genus Tera-toscincus 0.57% (Macey et al., 1999b). The calibrations derived from hynobiid salamanders and Laudakia lizards are each based on four geologic dates and are therefore the most reliable calibrations, suggesting a pairwise rate of change of 1.3% sequence divergence per million years.

Applying this calibration yields an age of approximately 8 million years for the R. boylii species group (Table 4). Case (1978), using the immunological distance/time relationship of Wilson et al. (1977), found the age of the group to be approximately 12 million years, which is slightly older than our estimate derived from mitochondrial DNA. Case (1978) suggested that the R. boylii species group diverged from the R. temporaria species group approximately 27 million years before present (MYBP). Using the mitochondrial DNA sequence data and the rate of sequence evolution given above, this divergence is dated at approximately 12 MYBP. However, after 10 million years, mitochondrial DNA is expected to saturate (Moritz et al., 1987); hence, a linear relationship of nucleotide substitutions with time is not anticipated. Therefore, the date of 12 MYBP is likely to be an underestimate of this divergence, but still not congruent with the date of 27 MYBP suggested by Case (1978).

Geographic Fragmentation within R. muscosa

The phylogenetic analysis of mitochondrial DNA sequences reveals two major clades within R. muscosa (Fig. 5). A northern clade contains populations from the northern and central Sierra Nevada, and a southern clade contains populations from the southern Si-

* Percentage sequence divergence is shown above the diagonal, and number of base substitutions between sequences is shown below the diagonal. Rana muscosa populations are numbered as under Materials and Methods and are abbreviated as follows: R. muscosa-1, north Plumas Co.; R. muscosa-2, south Plumas Co.; R. muscosa-3, Alpine Co.; R. muscosa-4, Tuolumne Co.; R. muscosa-5, Fresno Co.; R. muscosa-6, San Gabriel Mtns.; R. muscosa-7, San Jacinto Mtns.; and R. muscosa-8, San Bernardino Mtns.

Relationships and Timing of Divergence Among R. muscosa Populations

FIG. 5. Map showing locations of R. muscosa populations sampled in California. Samples are numbered as in Fig. 1 and under Materials and Methods. The four major clades are labeled on branches of the phylogenetic tree to the right. Suggested dates of divergence between the clades are derived by applying the pairwise rate of 1.3% sequence divergence per million years. Note the similarity in timing of divergence at approximately 1.5 million years within each of the two major clades.
erra Nevada and mountain ranges in southern California (San Gabriel, San Jacinto, and San Bernardino). This phylogenetic hypothesis suggests that Sierra Nevada populations do not form a monophyletic group; monophyly of these populations is rejected by the Wilcoxon signed-ranks test (Table 3).

The biogeographic break in the Sierra Nevada discovered in _R. muscosa_ is congruent with a pattern of fragmentation between northern and southern populations that is observed among codistributed amphibian and reptilian species (Table 5, Fig. 6). The break observed in _R. muscosa_ occurs between Kings Canyon National Park and a region slightly north of Yosemite National Park. This pattern is broadly congruent with genetic breaks between central and southern Sierra Nevada populations of the toad _Bufo canorus_ (Shaffer et al., 2000), the salamander _Ensatina eschscholtzii_ (Moritz et al., 1992), the snake _Lampropeltis zonata_ (Rodríguez-Robles et al., 1999), and the newt _Taricha torosa_ (Tan and Wake, 1995). Hence, there are now five species of amphibians and reptiles with a similar pattern of biogeographic fragmentation in the Sierra Nevada, suggesting that these species were influenced by a common vicariant event.

The timing of divergences within _R. muscosa_ is useful for understanding biogeographic fragmentation in the Sierra Nevada of California. Applying the pairwise rate of change of 1.3% sequence divergence per million years to the _R. muscosa_ populations, the initial divergence between the northern and the southern clades is dated at approximately 2.2 MYBP. Within each of these clades, temporal patterns of divergence are strikingly similar. The timing of divergence observed between populations from the northern Sierra Nevada and central Sierra Nevada (1.5 MYBP) appears to coincide in timing with the divergence observed between the southern Sierra Nevada population and the southern California populations (1.4 MYBP). This result suggests that initial divergence within _R. muscosa_ occurred in the Sierra Nevada during the late Pliocene, and that further divergence within each of the northern and southern clades occurred in the Pleistocene. The fact that divergences within the northern and southern clades coincide in timing suggests a common vicariant event, such as climatic effects of Pleistocene glaciation.

The three populations in the mountains of southern California are isolated by arid valleys. However, the similarity of mitochondial DNA sequences (Table 4) derived from these populations indicates recent con-

* Counties in the Sierra Nevada of California are listed across the top of the table from north to south (see Fig. 6). N and S refer to the southernmost extent of the northern mitochondrial haplotypes and the northernmost extent of the southern mitochondrial haplotypes, respectively. Data are from Moritz et al. (1992; _E. eschscholtzii_), this study (_R. muscosa_), Shaffer et al. (2000; _B. canorus_), Rodríguez-Robles et al. (1999; _L. zonata_), and Tan and Wake (1995; _T. torosa_).
tact, probably over the last few hundred thousand years.

Implications for Conservation of R. muscosa

Biogeographic studies documenting genetic fragmentation within species ranges can be helpful in making conservation decisions. The high-elevation frog, R. muscosa, occurs in some of the most pristine habitats in North America, but extinction of populations is occurring rapidly (Vredenburg et al., 2001). The divergences found within R. muscosa suggest at least four evolutionarily distinct units within the species. Statistical support for evolutionarily distinct populations from the northern Sierra Nevada, central Sierra Nevada, southern Sierra Nevada, and southern California mountains is obtained (Table 3). Only a single population still exists in each of the San Gabriel, San Jacinto, and San Bernardino Mountains of southern California with less than 200 adults among the three populations, making conservation of these populations a management priority (Vredenburg et al., 2001). Populations in the central and northern Sierra Nevada are also close to extinction (Vredenburg et al., 2001). Only in the southern Sierra Nevada are there any apparently healthy populations remaining, but they are few in number (three or four populations; Vredenburg et al., 2001). More sampling is needed throughout the Sierra Nevada to delineate the boundaries of the three potential management units (Moritz, 1994; Moritz and Faith, 1998) identified here. Work in the Sierra Nevada should be conducted rapidly, as the central Sierra Nevada population sampled from Tuolumne County for this study is already extinct. The fact that R. muscosa, a species occurring primarily on pristine government land, is on the verge of extinction throughout its range demonstrates that land acquisition is only a first step in the preservation of species and suggests that more work must be done to understand the mechanisms behind population declines. Conservation research should apply phylogenetic analyses to delimit management units in conjunction with field studies that test mechanisms driving population declines.

ACKNOWLEDGMENTS

We thank Carla Cicero, Jens Vindum, and David B. Wake for tissue samples, and Nikolai Orlov and Theodore J. Papenfuss for field assistance. This work was supported by grants from the National Science Foundation (DEB-9726064 to A.L., J.R.M. and Theodore J. Papenfuss), National Geographic Society (4110-89 and 4872-93 to Theodore J. Papenfuss and J.R.M.), the California Academy of Sciences, predoctoral fellowships from the Howard Hughes Medical Institute to J.L.S. and J.A.B., and USGS-WERC (00WRS0023 to V.V.).

APPENDIX

Alternative hypotheses used in Wilcoxon signed-ranks tests (Felsenstein, 1985; Templeton, 1983). Lengths of trees are given in parentheses. Taxa are labeled as in Fig. 1.

The most parsimonious tree derived by constraining the R. boylii group not to form a monophyletic group (length of 1253 steps): A1. (R. catesbeiana, (R. sylvatica, (R. temporaria, (R. pretiosa, (R. aurora, (R. cascadae, ((N. Plumas Co.-1, S. Plumas Co.-2), (Alpine Co.-3, Tuolumne Co.-4)), (Fresno Co.-5, ((San Gabriel Mtns.-6, San Jacinto Mtns.-7), San Bernardino Mtns.-8)))))), R. boylii)).

The most parsimonious tree derived by constraining R. boylii and R. muscosa to form a monophyletic group (length of 1264 steps): B1. (R. catesbeiana, (R. sylvatica, (R. temporaria, (((R. boylii, (((N. Plumas Co.-1, S. Plumas Co.-2), (Alpine Co.-3, Tuolumne Co.-4)), (Fresno Co.-5, ((San Gabriel Mtns.-6, San Jacinto Mtns.-7), San Bernardino Mtns.-8)))), R. aurora, (R. cascadae), R. pretiosa))).

The most parsimonious tree derived by constraining R. muscosa populations from the Sierra Nevada to form a monophyletic group (length of 1247 steps): C1. (R. catesbeiana, (R. sylvatica, (R. temporaria, ((R. boylii, R. pretiosa), (R. aurora, (R. cascadae, (((N. Plumas Co.-1, S. Plumas Co.-2), (Alpine Co.-3, Tuolumne Co.-4)), (Fresno Co.-5, ((San Gabriel Mtns.-6, San Jacinto Mtns.-7), San Bernardino Mtns.-8))))))).

The most parsimonious tree derived by constraining R. muscosa populations from the northern Sierra Nevada not to form a monophyletic group (length of 1251 steps): D1. (R. catesbeiana, (R. sylvatica, (R. temporaria, (R. boylii, R. pretiosa), (R. aurora, (R. cascadae, (((N. Plumas Co.-1, S. Plumas Co.-2), (Alpine Co.-3, Tuolumne Co.-4)), (Fresno Co.-5, ((San Gabriel Mtns.-6, San Jacinto Mtns.-7), San Bernardino Mtns.-8)))))), ((R. aurora, (R. cascadae)), R. pretiosa))).

The most parsimonious tree derived by constraining R. muscosa populations from the central Sierra Nevada not to form a monophyletic group (length of 1252 steps): E1. (R. catesbeiana, (R. sylvatica, (R. temporaria, (R. boylii, R. pretiosa), (R. aurora, (R. cascadae, (((N. Plumas Co.-1, S. Plumas Co.-2), (Alpine Co.-3, Tuolumne Co.-4)), (Fresno Co.-5, ((San Gabriel Mtns.-6, San Jacinto Mtns.-7), San Bernardino Mtns.-8)))))),((R. boylii, R. pretiosa), (R. aurora, (R. cascadae, (((N. Plumas Co.-1, S. Plumas Co.-2), (Alpine Co.-3, Tuolumne Co.-4)), (Fresno Co.-5, ((San Gabriel Mtns.-6, San Jacinto Mtns.-7), San Bernardino Mtns.-8))))))).

The most parsimonious tree derived by constraining R. muscosa populations from southern California not to form a monophyletic group (length of 1252 steps): F1. (R. catesbeiana, (R. sylvatica, (R. temporaria, (R. boylii, R. pretiosa), (R. aurora, (R. cascadae, (((N. Plumas Co.-1, S. Plumas Co.-2), (Alpine Co.-3, Tuolumne Co.-4)), (Fresno Co.-5, San J acinto Mtns.-7), San Bernardino Mtns.-8)))))), ((Fresno Co.-5, San J acinto Mtns.-7), San Bernardino Mtns.-8), San Gabriel Mtns.-6))))).
